Fire coral persistent cutaneous reaction

M. Paradisi, A. Grassi, G. Conti, F. Passarelli and M.G. Cacciaguerra

Summary

A patient who developed a persistent cutaneous reaction to fire coral is presented. Treatment with topical corticosteroids reduced the severity of the lesion but after a follow-up period of 18 months no complete resolution has been showed.

Introduction

Red Sea Coral ("stinging" or "fire coral") is a coelonterate of the Milleporina order and of the Hydrozoan class. It derives its name because it releases nematocysts, toxic organelles responsible for cutaneous lesions, immediately after contact with skin.

All coelenterates are invertebrate organisms composed of a double epithelial layer, which delimits a cavity, the "coelenterium". Their venomous apparatus is composed of the nematocysts, toxin-releasing organelles composed of a capsule and tube, located in large numbers on the tentacles and made-up of collagen-like material. The venom is ejected by the capsule of the nematocyst through the long filamentous tube into the victim's body (1).

Toxic substances in the venom include quaternary ammonium compounds, proteins, 5-hydroxytryptamine, catecholamines, histamine and histamine liberators.

The cutaneous lesions are induced by the toxic substances liberated and by the foreign-body reaction to the fragments of calcium carbonate, which are in the tentacles that hurt the skin (2). Moreover, the skin scars are accompanied by burn and/or pain.

The severity of the cutaneous reactions depends on the number of the nematocysts discharged, the venom toxicity, the intensity of the stinging and the individual sensibility (3). The general symptoms, which have been reported, include nausea, vomiting, abdominal pain, diarrhea, muscle spasm, respiratory difficulty, tachycardia, hypotension and fever (1,4).

In the majority of cases soon after the contact with the fire coral an erythematosus reaction appears, which spontaneously heals in about two months. Sometimes there is a lesional polymorphism. Soon after contact to a fire coral an acute vesiculo-bullous dermatitis follows; then there is a subacute granulomatous dermatitis and,
in the last phase, a chronic lichenoid dermatitis.
Some authors have described a delayed or recurrent
granulomatous-like or sarcoid-like cutaneous reaction
after a period of up to 12 months from the fire coral
contact (5). In some patients the coelenterate's induced
cutaneous reaction can be delayed by the use of
systemic corticosteroids (6).

Case report

A 41-year-old man with a personal history of
gastroduodenitis came to our observation in September
1996 for an eczematous lesion on the right arm.
He reffered that during the month of July, while
swimming off the Red Sea, he had touched a coral well
known as “fire coral” with his right arm (Fig. 1). Immedi-
ately an acute erythematous and edematous dermatitis
with burning and pruritus developed on the site of
contact.
Under antihistaminic therapy he noticed a marked
reduction of the edema soon after 3 days, but the eczema-
tous dermatitis persisted even under topical therapy
with betamethasone dipropionate.
When the patient presented to us we noticed an
erthematous-infiltrated, well-demarcated, 25X5 cm
plaque, on the lateral surface of the right arm.
A biopsy of the lesion showed a dense perivascular
infiltrate composed by lymphocytes, histiocytes and
some eosinophils in the papillary and mid dermis.
Superficial blood vessels were slightly dilated (Fig. 2).
Histiocytes were mixed together with lymphocytes;
there was no granuloma formation. The epidermis
showed a slight ortho- and parakeratosis and some
neutrophils in the stratum corneum. Immunohisto-
chemical study revealed a T phenotype of all lympho-
cytes.
Because of the gastroduodenitis the patient received
no systemic steroids but only topical application of
clobetamethasone dipropionate twice a day, on alternate
weeks for two months. The skin lesions healed
only partially with persistence of the lesion up to the
next four months.

Discussion

With this report we want to stress the characteristic
of the cutaneous lesions induced by the “fire coral” due
to the poor attention received in the dermatologic lit-
terature.
It has been observed that while the cutaneous les-
ions which appear soon after the contact with the “fire
coral” depend on the venom toxicity, the delayed or
recurrent lesions could be caused by a delayed hyper-
sensitivity response to an antigenic compound of the
coelenterate’s nematocyst. Some authors propose a type I hypersensitivity associated with a type IV allergy (7).

An immunohistochemical study reveals that Langerhans cells and T lymphocytes may play a role in the cutaneous eruptions to coelenteretes (8).

In particular, in our case the histologic studies showed a chronic unspecific dermatitis without granuloma and almost without epidermal changes.

Contact with this coral can produce three types of cutaneous reactions: an acute urticaria-like, hemorrhagic or ulcero-necrotic reaction associated or not to anaphylaxis, a leukocytoklastic-like vasculitis and, in many of these latter cases, a delayed response of type IV. Most probably our case can be included into this last group.

All these data have been confirmed by many studies on the serologic response of individuals who had touched the “fire coral”. All patients demonstrated a higher titer of circulating specific antibodies against the coelenterate’s antigens.
