Aspergillus terreus postoperative endophthalmitis

Taraprasad Das, Prateep Vyas, Savitri Sharma

Aspergillus endophthalmitis has been reported in drug abusers, in immunosuppressed hosts, following intraocular surgery, and after trauma. Usually Aspergillus flavus,\(^1\) \(^2\) Aspergillus fumigatus,\(^3\) and Aspergillus nidulans\(^4\) are implicated as the offending organisms. Recently Aspergillus terreus endophthalmitis has been reported in a patient with chronic lymphocytic leukaemia.\(^5\) We describe a case of postcataract surgery Aspergillus terreus endophthalmitis who was successfully treated with vitrectomy, and intraocular and systemic antifungal antibiotics. To our knowledge this is the first reported case of postoperative endophthalmitis caused by this species of Aspergillus.

Case report

A 50-year-old man gave a history of uneventful intracapsular cataract extraction in left eye 4 weeks before presenting to us. His early postoperative period was reported to be uneventful. Four weeks later he experienced pain, redness, and reduction in vision in the same eye. He was diagnosed to have postoperative endophthalmitis and referred for further management. On examination visual acuity in the operated eye was perception of light with accurate projection. The eye was relatively quiet with some hyperaemia of the conjunctiva. The cornea showed a small amount of stromal oedema with few keratic precipitates. The anterior chamber showed a moderate (2+) reaction. At the 6 o'clock position behind the iris in the anterior vitreous a white fluffy mass with feathery edges was seen (Fig 1A). A moderately good fundal glow was present with opacities in the mid vitreous and inferiorly. He was confirmed clinically to have postoperative endophthalmitis. After baseline renal function evaluation, intravenous gentamicin 80 mg three times a day and cefazolin 1 g four times a day was started. Topically 15% gentamicin and
Aspergillus terreus postoperative endophthalmitis

50% cefazolin eye drops were instilled every hour alternately. Within 8 hours of presenting to us three port standard vitrectomy was performed and an undiluted vitreous biopsy specimen was sent for microbiological evaluation.

The wet mount, Giemsa, and Gram’s stains were negative for bacteria and fungus. Intravitreal gentamicin 100 μg with cefazolin 2-25 mg and dexamethasone 360 μg were given at the end of surgery. A vitreous sample was cultured for aerobic and anaerobic bacteria and fungus on a number of media: blood agar, chocolate agar, Sabouraud’s dextrose agar, brain heart infusion broth, and thioglycollate broth (supplemented with vitamin K and haemin). After 48 hours’ incubation at 27°C Sabouraud’s dextrose agar grew white fluffy colonies with central cinnamon brown pigmentation. Microscopic examination of the culture confirmed it to be *Aspergillus terreus* (Fig 1B). The same fungus was grown on several media and no bacteria were grown.

As soon as the microbiology report was obtained 5 μg of amphotericin B was given intravitreally. Oral ketoconazole 200 mg three times a day and topical natamycin every 2 hours were started. Intravenous and topical antibiotics were withdrawn. However, topical steroids were continued. The patient responded well with gradual recovery of a healthy fundal glow. The fundus details were visualised after 2 weeks and systemic ketoconazole was discontinued in view of its potential liver toxicity. When seen on the last follow up 4 months after vitrectomy the best corrected visual acuity was 6/18 and the vitreous was clear (Fig 1C).

Comment

*Aspergillus* endophthalmitis is a relatively rare condition encountered in clinical practice. Endogenous *Aspergillus* endophthalmitis is reported in immunocompromised individuals. Exogenous *Aspergillus* endophthalmitis is reported following cataract surgery, keratoplasty, and eye trauma. *Aspergillus flavus*, *A fumigatus*, and *A nidulans* have been reported to be causative agents of exogenous and endogenous endophthalmitis.

Recently *Aspergillus terreus* was reported to cause endogenous endophthalmitis in a patient with chronic lymphocytic leukaemia. This was the first report of *Aspergillus terreus* endophthalmitis. The reason for infrequent reporting could be because *Aspergillus terreus* is often considered a laboratory contaminant.

The presentation of our patient with ocular pain and reduction in vision 4 weeks after surgery with localised involvement of anterior and mid vitreous was characteristic of fungal endophthalmitis. However, the direct examination of undiluted vitreous specimen was negative. Forty eight hours later the culture was positive and at this time only intravitreal amphotericin B was given. This was supplemented with oral ketoconazole and topical natamycin.

Four months following vitrectomy the patient had useful vision with no recurrence of infection. Because of the changing microbiology pattern of endophthalmitis, any organism cultured from vitreous should not be dismissed either as normal conjunctival flora or a laboratory contaminant.
