Photodissociation of the i-C₃H₇O radical is investigated using fast beam photofragment translational spectroscopy. Neutral i-C₃H₇O radicals are produced through the photodetachment of a fast beam of i-C₃H₇O⁻ anions and are subsequently dissociated using 248 nm (5.0 eV). The dominant product channels are CH₃ + CH₃CHO and OH + C₃H₆ with some contribution from H + C₃H₆O. CH₃ and H loss are attributed to dissociation on the ground electronic state of i-C₃H₇O, but in a nonstatistical manner because RRKM dissociation rates exceed the rate of energy randomization. Translational energy and angular distributions for OH loss are consistent with ground state dissociation, but the branching ratio for this channel is considerably higher than predicted from RRKM rate calculations. These results corroborate what has been observed previously in C₂H₅O dissociation at 5.2 eV that yields CH₃, H, and OH loss. Additionally, i-C₃H₇O undergoes three-body fragmentation to CH₃ + CH₃ + HCO and CH₃ + CH₄ + CO. These three-body channels are attributed to dissociation of i-C₃H₇O to CH₃ + CH₃CHO, followed by secondary dissociation of CH₃CHO on its ground electronic state.

Abstract:

Photodissociation of the *i*-C₃H₇O radical is investigated using fast beam photofragment translational spectroscopy. Neutral *i*-C₃H₇O radicals are produced through the photodetachment of a fast beam of *i*-C₃H₇O⁻ anions and are subsequently dissociated using 248 nm (5.0 eV). The dominant product channels are CH₃ + CH₃CHO and OH + C₃H₆ with some contribution from H + C₃H₆O. CH₃ and H loss are attributed to dissociation on the ground electronic state of *i*-C₃H₇O, but in a nonstatistical manner because RRKM dissociation rates exceed the rate of energy randomization. Translational energy and angular distributions for OH loss are consistent with ground state dissociation, but the branching ratio for this channel is considerably higher than predicted from RRKM rate calculations. These results corroborate what has been observed previously in C₂H₅O dissociation at 5.2 eV that yields CH₃, H, and OH loss. Additionally, *i*-C₃H₇O undergoes three-body fragmentation to CH₃ + CH₃ + HCO and CH₃ + CH₄ + CO. These three-body channels are attributed to dissociation of *i*-C₃H₇O to CH₃ + CH₃CHO, followed by secondary dissociation of CH₃CHO on its ground electronic state.

1. Introduction:

Alkoxy radicals (RO) are crucial players in atmospheric chemistry processes in which the oxidation of hydrocarbons propagates numerous reaction chains through interactions with O₂ and the NO_x cycle.^{1,2} Larger RO species have been implicated in autoignition chemistries,^{3,4} and the reactions of alkenes with OH radicals, through which RO radicals can be generated, are of relevant in combustion schemes.⁵ As such, understanding the fundamental properties and behaviors of these radicals is of general interest, and there is a wealth of information regarding the smallest RO radicals: CH₃O, C₂H₅O, C₃H₇O, and *t*-C₄H₉O.^{6,7} In our laboratory, we have previously investigated photodissociation of CH₃O and C₂H₅O;^{8,9} here, we present the results of *i*-C₃H₇O ((CH₃)₂CHO·) dissociation at 248 nm using fast radical beam photofragment translational spectroscopy and provide a comparison to results for the smaller alkoxy radicals.

i-C₃H₇O is of general interest as a larger member of the alkoxy family and can occur as multiple isomers as shown in Figure 1. *i*-C₃H₇O, as opposed to *n*-C₃H₇O, was chosen here due to the ease of generating its anionic precursor from isopropanol. Additionally, there is a larger body of work in the literature examining *i*-C₃H₇O, although *n*-C₃H₇O has not been entirely neglected. The simplest alkoxy radical CH₃O belongs to the C_{3v} point group with distinct $\tilde{X}(^2E)$ and $\tilde{A}(^2A_1)$ states separated in energy by several eV.^{6,8} However, in the *i*-C₃H₇O radical, the C_{3v} symmetry of methoxy (CH₃O) is broken due to the additional methyl groups. Therefore, the ground state is split into two nearly degenerate electronic states, which for *i*-C₃H₇O are the $\tilde{X}(^2A')$ and $\tilde{A}(^2A'')$ states.

The laser fluorescence spectrum of *i*-C₃H₇O was first measured by Foster et al.^{10,11} and revisited by Liu et al.¹² who characterized the $\tilde{B} \leftarrow \tilde{X}$ transition and determined the term value of the $\tilde{B}(^2A')$ state to be 27164.4 cm⁻¹. The authors found parallel-type line intensities associated with this transition and indicated that the ground electronic state of *i*-C₃H₇O is of *A'* symmetry, in contrast to the *A''* ground state of the ethoxy radical (C₂H₅O).¹² In addition to characterizing the higher-lying $\tilde{B}$ state, laser induced fluorescence determined the energetic splitting of the $\tilde{A}$ and $\tilde{X}$ states to be 60.4 cm⁻¹. Further exploration of the $\tilde{B} \leftarrow \tilde{X}$ and $\tilde{B} \leftarrow \tilde{A}$ transitions examined the effect of pseudo-Jahn-Teller distortion in vibronic coupling between the $\tilde{X}(^2A')$ and $\tilde{A}(^2A'')$ states.¹² The anion photoelectron spectrum of *i*-C₃H₇O⁻ has been measured previously,^{6,13} and the

electron affinity of the *i*-C₃H₇O radical was determined to be 1.847 ± 0.004 eV. As in the fluorescence spectrum, the photoelectron spectrum is complicated by vibronic coupling between the $\tilde{X}$ and $\tilde{A}$ states. Dillon et al.¹⁴ deconstructed the photoelectron spectrum and confirmed 68 cm⁻¹ as the $\tilde{A}$ and $\tilde{X}$ splitting.

There have been several studies examining the experimental association of OH + C₃H₆ (propene) that can, in principle, yield *i*-C₃H₇O.¹⁵⁻¹⁸ Numerous theoretical studies^{5,19} indicate that OH addition to the central carbon of propene yields CH₃CHOHC·H₂ that can then isomerize to *i*-C₃H₇O ((CH₃)₂CHO·). These studies implicate OH + C₃H₆ as a potential product channel for *i*-C₃H₇O dissociation.

The photodissociation of *i*-C₃H₇O has yet to be explored, but that of its close counterpart, C₂H₅O, has been investigated at 5.17 eV and 5.96 eV.⁹ The predominant photofragments observed were OH + C₂H₄ and CH₃ + CH₂O, and dissociation experiments of the isotopologue C₂D₅O identified D + C₂D₄O as a valid product channel.⁹ No three-body dissociation was observed.

In this work, photofragment translational spectroscopy was used to examine the photodissociation of *i*-C₃H₇O at 248 nm (5.0 eV). Equations 1 through 11 present the possible product channels at this energy.^{5,6,21}

Figure 1 shows the lower energy two-body product channels and the pathways through isomers CH₃C·(OH)CH₃ (hydroxy carbenyl) and/or CH₃CHOHC·H₂ (hydroxy propenyl). The

predominant two-body channel observed is consistent with channel 1 ($\text{CH}_3 + \text{CH}_3\text{CHO}$) with some contribution from channel 5 ($\text{OH} + \text{C}_3\text{H}_6$) and a H loss channel, either channel 2 ($\text{H} + (\text{CH}_3)_2\text{CO}$) or 4 ($\text{H} + \text{C}_3\text{H}_5\text{OH}$). Additionally, a small amount of three-body dissociation is observed through channels 9 ($\text{CH}_3 + \text{CH}_4 + \text{CO}$) and 10 ($\text{CH}_3 + \text{CH}_3 + \text{HCO}$) through secondary dissociation of acetaldehyde.

Figure 1: Potential energy surface for the lowest energy two-body dissociation pathways of *i*-C₃H₇O. The product energies are determined from experimental heats of formation.²¹ The energies of structures and transition states marked by a red line were acquired from Reference 5.

2. Experimental Methods:

The fast radical beam instrument has been presented in detail elsewhere.²²⁻²⁴ In brief, 40 psig of Ar/He was bubbled through isopropanol (99.5% Millipore) and expanded into vacuum through a pulsed Amsterdam Piezovalve^{24,25} operating at 100 Hz. *i*-C₃H₇O⁻ anions were generated when the gas was expanded through a DC discharge grid. The anions were accelerated to 6-8 keV,

mass selected using a Bakker time-of-flight mass spectrometer,^{26,27} compressed, and steered. A light pulse at 532 nm (2.33 eV) from a Nd:YAG (Litron 742-100) laser or 655 nm from a Nd:YAG-pumped dye laser (Radiant Dyes Narrowscan) intersected the anions and detached an electron to generate a fast beam of *i*-C₃H₇O radicals. Deuterated experiments were performed in a similar manner using deuterated isopropanol (99.5% Sigma Aldrich) as a precursor.

A photoelectron spectrometer perpendicular to the molecular beam direction measured the kinetic energy of the detached electrons. Following detachment, electrons were velocity-map-imaged on to a microchannel plate detector coupled to a phosphor screen and CCD camera (Beam Imaging Solutions BOS-75).²² The acquired images were analyzed using the Inverse Abel transformation (BASEX).²⁸ Multiple detachment wavelengths (λ_{detach}) were used to properly minimize the internal energy of the resultant *i*-C₃H₇O radicals and characterize its effect in the dissociation results.

Following photodetachment, *i*-C₃H₇O radicals were intersected by 248 nm (5.0 eV) light from a GAM EX50 excimer laser. Two- and three-body fragments were collected in coincidence using a time-and-position sensitive Roentdek Hex80 delay-line detector.^{29,30} A 2.9 mm radius beam block near the center of the detector face prevented undissociated radicals from impinging upon the detector. The arrival times and positions of fragments in coincidence were used to generate photofragment mass, translational energy, and angular distributions. The translational energy distributions presented here have been corrected using a detector acceptance function (DAF) to account for the beam block and finite size of the detector.²²

The translational energy and angular distributions are given by

$$P(E_T, \theta) = P(E_T) \cdot [1 + \beta(E_T)P_2(\cos \theta)] \quad (12)$$

in which $\beta(E_T)$ is the energy-dependent anisotropy parameter and $P_2(\cos \theta)$ is the second Legendre polynomial.³¹ For experiments performed using linearly polarized light, θ is the angle between the electric field vector and dissociation recoil axis such that β_{lin} varies from -1 to 2 for perpendicular and parallel transitions, respectively. However, in our experiments, in which the output of the excimer laser is unpolarized, θ is the angle between the laser propagation direction and dissociation recoil axis (in the case of two-body dissociation) or the normal to the plane of

dissociation (in the case of three-body dissociation) such that β_{obs} varies from 1/2 to -1 for perpendicular and parallel transitions, respectively.²²

Due to the high product mass ratio (58:1) of channels that involve H loss (channel 2 or 4), these channels cannot be detected in coincidence because the H atom generally scatters beyond the detector and the heavy fragment hits the beam block. However, for events with sufficient translational energy release, the heavy fragment can travel enough distance in the plane parallel to the detector to clear the beam block and be detected. By collecting the time-of-flight distribution of all fragments that hit the detector, we can learn about H loss channels through simulations. This measurement is more effective for the deuterated isotopologue and is discussed in Section 3.d.

3. Results:

a. Anion photoelectron spectrum

The anion photoelectron spectrum of $i\text{-C}_3\text{H}_7\text{O}^-$ is presented in Figure 2. The black trace is the experimental distribution using a detachment wavelength of 532 nm.

Figure 2: Photoelectron spectrum of $i\text{-C}_3\text{H}_7\text{O}^-$ at 532 nm as a function of electron kinetic energy (eKE).

The largest feature, peak a, corresponds to the vibrational origin (the 0-0 transition) yielding an electron affinity of 1.836 ± 0.005 eV that matches previously reported values.^{6,13} Hence we can identify the radical produced by photodetachment to be $i\text{-C}_3\text{H}_7\text{O}$. The photoelectron spectrum is consistent with that reported by Ramond et al.⁶ who observed an intense, well-defined feature corresponding to the origin and numerous less-defined peaks at lower kinetic energies.

Specifically, the features labelled b and c in Fig. 2 were assigned to one quantum of excitation in the CCC bend and the CCCO symmetric bending mode, respectively. Dillon et al.¹⁴ later simulated the photoelectron spectrum to include non-adiabatic coupling and identified the $\tilde{A}^2A'' \leftarrow \tilde{X}^2A'$ splitting as 68 cm⁻¹, a value that is consistent with other bodies of work.^{8,12,32}

The photoelectron spectrum can also be used to characterize the internal energy of the generated radical. In Fig. 2, $\lambda_{detach} = 532$ nm (2.33 eV) which is ~ 0.5 eV above the electron affinity of *i*-C₃H₇O. Despite this, most of the radicals are generated in their ground vibrational state, as is evident by the dominant vibrational origin. The majority of the dissociation data presented in the following sections is for experiments performed with $\lambda_{detach} = 655$ nm (1.89 eV), which is just above the electron affinity of *i*-C₃H₇O. We thus approximate the internal energy of the *i*-C₃H₇O radicals E_{INT}^R to 0 eV in subsequent analysis.

b. Mass distributions

Figure 3: Two-body (a) and three-body (b) mass distributions of *i*-C₃H₇O dissociation via 248 nm. The black traces present the results of *i*-C₃H₇O dissociation, and the red traces present the results of *i*-C₃D₇O dissociation.

Figure 3 presents the mass distributions for dissociation of *i*-C₃H₇O (black traces) and *i*-C₃D₇O (red traces) at 248 nm. Fig. 3a shows the two-body mass distribution in which the black trace exhibits narrow features around 15 Da and 44 Da with distinctive shoulders on each peak. The main peaks at 15 Da and 44 Da correspond to CH₃ and C₂H₄O. As such, these features are due to either channel 1 (CH₃ + CH₃CHO) or 3 (CH₃ + C₂H₃OH). The shoulders on the main features extend to ~ 17 Da and 42 Da and thus suggest the formation of O + C₃H₇ (channel 8), OH + C₃H₆

(channel 5) or both. In dissociating *i*-C₃D₇O, which is shown in red, the lower mass peak shifts to 18 Da, and the higher mass peak shifts to 48 Da. These shifts are consistent with the formation of channel 1 and/or 3 in which CH₃ (15 Da) shifts to CD₃ (18 Da), and the C₂D₄O co-fragment appears at 48 Da. Additionally, the shoulder in the red trace is less distinct, suggesting that the mass of the secondary channel is identical to channel 1 or 3 upon deuteration (18 Da and 48 Da), thereby confirming the assignment of channel 5 (OH + C₃H₆). To further analyze these results, the mass distributions were simulated using the translational energy distributions of channels 1 and 5 and were found to be consistent with the experimental results. These are presented in Figure S1 in the supplementary material and confirm the absence of channel 8.

Figure 3b presents the three-body mass distribution for the dissociation of *i*-C₃H₇O (black) and *i*-C₃D₇O (red) at 248 nm. The most noticeable feature in the black trace is a peak around 15-16 Da that is ~3-4 times more intense than any other feature. In examining the possible three-body product channels, 9-11, one can see that CH₃ is a product for all three channels. The second fragment for channels 9 (CH₃ + CH₄ + CO) or 10 (CH₃ + CH₃ + HCO) is either CH₄ or CH₃, respectively. Thus, the presence of a second fragment attributed to either CH₃ or CH₄ explains the intensity of this main feature. Additionally, there is a broad feature spanning ~26-31 Da which could be from CO (28 Da), HCO (29 Da) or both.

The photodissociation of *i*-C₃D₇O is again useful in assessing the contributions of channels 9 and 10. The red distribution is significantly noisier than the black one owing to substantially fewer coincidence events collected for the deuterated radical. The peak at 15 Da (CH₃) shifts to 18 Da as expected, but it also noticeably widens, which would occur if we were observing both CD₃ (18 Da) and CD₄ (20 Da). Furthermore, the broad feature spanning 28-29 Da is slightly extended on the high-mass edge in the deuterated distribution, which might occur if both CO (28 Da) and DCO (30 Da) were present. As such, the deuterated distribution suggests that both channel 9 and 10 are formed.

Finally, there is a feature at 1 Da (corresponding to the H atom) and 43 Da (C₂H₃O) which could be from channel 11 (H + CH₃ + C₂H₃O). However, in examining the deuterated distribution, it is not obvious that a shift from 1 Da (H) to 2 Da (D) is present. Additionally, coincident

dissociation events resulting in H atom loss are often suspect in our experiment as they can arise from false coincidence events associated with the challenges of detecting H atoms in our experimental setup. Indeed, false coincidence simulations, presented in Figure S2 of the supplementary material, lead us to conclude that most of this signal at 1 Da results from artifacts of the detection scheme rather than true channel 11 formation. As such, it will not be discussed further.

c. Translational energy distributions

The translational energy imparted to photofragments is given by

$$E_T = h\nu - D_0 + E_{\text{INT}}^{\text{R}} - E_{\text{INT}}^{\text{P}} \quad (13)$$

in which E_T is the translational energy of the photofragments, $h\nu$ is the photon energy (5.0 eV), D_0 is the product channel dissociation energy, $E_{\text{INT}}^{\text{R}}$ is the internal energy of the initial $i\text{-C}_3\text{H}_7\text{O}$ radical, and $E_{\text{INT}}^{\text{P}}$ is the internal energy of the photofragments. As was discussed in Section 3.a, we approximate $E_{\text{INT}}^{\text{R}}$ to be 0.

Figure 4: The translational energy distribution of $i\text{-C}_3\text{H}_7\text{O}$ dissociation to channel 1 or 3 ($\text{CH}_3 + \text{CH}_3\text{CHO}$ or $\text{C}_2\text{H}_3\text{OH}$) is shown in panel a in which $\lambda_{\text{detach}} = 655$ nm. Panel b shows the dissociation of $i\text{-C}_3\text{H}_7\text{O}$ to channel 5 ($\text{OH} + \text{C}_3\text{H}_6$). The maximum available energies ($E_{\text{T,MAX}}$) for channels 1 and 3 are beyond the scale of the x-axis and thus not shown in panel a but that for channel 5 is marked by the blue arrow in panel b.

Figure 4 shows the translational energy distributions of $i\text{-C}_3\text{H}_7\text{O}$ dissociation to channel 1 or 3 ($\text{CH}_3 + \text{CH}_3\text{CHO}$ or $\text{C}_2\text{H}_3\text{OH}$) in panel a and dissociation to channel 5 ($\text{OH} + \text{C}_3\text{H}_6$) in panel b.

In panel a, the distribution is generally broad and peaks around ~ 1.0 - 1.5 eV, far below the maximum available energy, $E_{T,MAX}$, which is 4.71 eV and 4.28 eV, for channels 1 and 3, respectively. The anisotropy parameter associated with the main body of the high energy peak is $\beta_{obs} = 0.11 \pm 0.05$ (1- σ error bar) which corresponds to $\beta_{lin} = -0.22 \pm 0.10$. This value is consistent with a perpendicular electronic transition, although the anisotropy is quite weak.

Also noticeable in Figure 4a is a small, broad peak from 0-0.5 eV. Experiments performed with the dissociation laser off indicate that this feature actually stems from dissociation from the detachment laser alone, i.e. a second photon from that laser is absorbed by the radical created by photodetachment. Figure S3a in the supplementary material compares the translational energy distributions for channel 1/3 formation at detachment wavelengths of 532 nm (2.33 eV) and 655 nm (1.89 eV). In the distribution for 532 nm, there is an intense feature peaking around 0.25 eV that mostly disappears in the 655 nm distribution. Moreover, in acquiring dissociation data from the 532 nm detachment laser only, we clearly see in Figure S3b that this low translational energy peak is due to the detachment laser. Therefore, we do not consider the low energy peak in our analysis. Finally, if the C_2H_4O isomer corresponds to CH_3CHO (acetaldehyde) of channel 1, then any events in which the translational energy release is less than 1.05 eV can yield secondary dissociation of the acetaldehyde to channels 9 or 10. As such, this lower energy feature would not likely appear in the distribution, consistent with assigning it to photodissociation from the detachment laser pulse.

Fig. 4b presents the translational energy distribution for formation of channel 5 ($OH + C_3H_6$). The distribution peaks around 0.5 eV, and tails off by 2.0 eV, well below the blue arrow denoting $E_{T,MAX}$ at 3.92 eV. Channel 5 is also affected by dissociation from the detachment laser only, but as previously indicated, this occurs minimally at $\lambda_{detach} = 655$ nm and therefore is not considered a major component of Fig. 4b. The associated angular distribution has $\beta_{obs} = -0.06 \pm 0.13$ and is thus isotropic within our error bars.

a)

b)

Figure 5: The translational energy distributions of *i*-C₃H₇O dissociation to channel 9 (CH₃ + CH₄ + CO) in panel a and channel 10 (CH₃ + CH₃ + HCO) in panel b. The results for experiments performed at $\lambda_{detach} = 532$ nm and $\lambda_{detach} = 655$ nm are presented in green and orange, respectively, for comparison. The blue arrow marks the maximum available energy, $E_{T,MAX}$, for channel 10. $E_{T,MAX}$ for channel 9 is off the scale of the x-axis.

Figure 5 presents the translational energy distribution for three-body dissociation channels 9 (CH₃ + CH₄ + CO) and 10 (CH₃ + CH₃ + HCO). Distributions are presented for experiments in which $\lambda_{detach} = 655$ nm (orange trace) and $\lambda_{detach} = 532$ nm (green trace) to demonstrate the effect of the detachment wavelength. In Fig. 5b, the orange trace tails off at a slightly lower energy than the green trace, but this is not quite as distinct in Fig. 5a. Both sets of distributions look markedly similar, peaking around 0.75 eV and mostly tailing off by $E_{T,MAX}$. However, in Fig. 5a there is a high energy tail that extends out to about 3 eV for both detachment wavelengths and is mostly absent in Fig. 5b. Due to the low raw experimental counts of these two channels, the anisotropy parameters are not included here.

In Fig. 5b, the distributions for channel 10 formation extend slightly beyond $E_{T,MAX}$, but this can be explained by possible contamination by events of channel 9. Because channels 9 and 10 have products very close in mass, it is likely that some CH_3 is identified as CH_4 and vice versa. This scenario has been observed in our experiment previously for three-body channels with fragments close in mass.^{33,34} As such, the similarity of distributions presented in Fig. 5a and 5b is not entirely surprising. Nonetheless, the high energy tail in Fig. 5a suggests that channel 9 is definitely present and is somewhat distinguishable from channel 10.

Three-body dissociation events in our experiment can be further analyzed using Dalitz plots³⁵ in which the fraction of translational energy imparted to each fragment in a three-body event is characterized. Figure 6 presents the Dalitz plots for channel 9 (panel a) and channel 10 (panel b) formation. ε_i represents the fraction of translation energy imparted to each fragment where $0 \leq \varepsilon_i \leq 1$. Because channel 10 has two fragments of the same mass, events are only plotted for one of the fragments in Fig. 6b. There is a broad swatch of intensity at the right edge of the ellipse (highlighted by the pink dashed line) where the maximum fraction of translational energy is imparted to the CH_3 fragment and the remainder is relatively uniformly distributed across the other two fragments.

The plot in Fig. 6a looks similar to that of Fig. 6b except that because each fragment has a different mass, the entire ellipse is plotted and is semi-symmetric about the blue line. There is a broad area of intensity on each edge of the ellipse, again symmetric about the blue line. However, as discussed earlier, the possible misassignment of CH_3 and CH_4 fragments may indicate that one side of the ellipse exhibits intensity that is really due to the alternate fragment. Both channels 9 and 10 contain a CH_3 fragment and thus a possible mechanism to these channels is the loss of this CH_3 radical in tandem with or followed by the dissociation of CH_3CHO . Thus, it is plausible that the Dalitz plots would exhibit similar swatches of intensity. In both plots, the intensity at the right edge of the ellipse implies a high fraction of translational energy imparted to the CH_3 fragment (red arrow).

Figure 6: Dalitz Plots for three-body dissociation of *i*-C₃H₇O into channel 9 (CH₃ + CH₄ + CO) in panel a and channel 10 (CH₃ + CH₃ + HCO) in panel b.

Three-body dissociation events can be concerted or sequential.³⁶ Concerted mechanisms are further categorized into synchronous, in which three-fragments form spontaneously, or asynchronous concerted, in which three-fragments are formed on a timescale less than a rotational period of the molecule. Sequential events are those in which two distinct dissociation events occur, ultimately yielding three fragments. Sequential events are generally identified by the partitioning of a relatively constant fraction of the translational energy to one fragment. This is observed in both panels of Figure 6. As discussed in the preceding paragraphs, the first CH₃ fragment (red arrow) receives a generally high fraction of the total translational energy, which is indicative of it leaving first, followed by dissociation of the remaining CH₃CHO fragment.

d. Noncoincidence time-of-flight simulations

It has been shown previously that the photodissociation of CH₃O and C₂H₅O yield two-body H loss.^{8,9,37} As such, we would like to understand if/in what quantity H + C₃H₆O is formed in *i*-C₃H₇O dissociation. In coincident detection, it is challenging to detect both fragments in an H loss event because of their large mass ratio; in general, the light fragment scatters beyond the detector and the heavy fragment does not clear the beam block. Furthermore, the H atom has low translational energy in the laboratory frame so its detection efficiency is low (on the order of 0.08).^{8,38} However, with sufficient translational energy release, the heavy fragment clear the beam block and hit the detector. As such, we can examine the all-fragment time-of-flight data to understand the contributions from each of our coincidence channels, and other fragments

detected not in coincidence (i.e. the heavy fragment from an H loss channel). We carried out this procedure for the *i*-C₃D₇O results where the smaller fragment mass ratio for D atom loss allows for greater chance of detecting the heavy fragment.

Figure 7 compares the experimental time-of-flight distribution (black dots) to a simulation (red dots). The simulation assumes a beam energy of 6 keV, and the arrival times are referenced to the detector gate timing (the x-axis scale of 200-800 ns does not present the actual flight time but rather the arrival time for the window of detection).

Figure 7: Experimental (black) and simulated (red) all fragment time-of-flight distributions of *i*-C₃D₇O to determine contribution of D atom loss. The blue trace is the simulated time-of-flight distribution for channels 1 (CD₃ + CD₃CDO), 5 (OD + C₃D₆), 9 (CD₃ + CD₄ + CO) and 10 (CD₃ + CD₃ + DCO) and includes two- and three-body coincident events in addition to contributions from true events in which only one or two fragments hit the detector, out of two and three, respectively. The orange plot is that of the contribution from the D + C₃D₆O, for which coincident detection is not probable. Any D atoms that hit the detector are spread out in time, but the heavy fragment has a narrow distribution of arrival times, as shown in the orange trace. Some noise has been factored in as well. The inset presents the translational energy distribution used to simulate the D + C₃D₆O channel with the maximum available energy for this channel marked by the dashed blue line.

The experimentally determined translational energy and angular distributions for the deuterated results of channels 1, 5, 9 and 10 were used to simulate the time-of-flight distributions for each channel. This component is shown in blue in Fig. 7. The orange trace in Fig. 7 presents the simulated contribution from D + C₃D₆O. No two-body coincident events for this channel are detected, but the heavy fragment, should it clear the beam block, arrives in a relatively narrow time interval as shown in the orange trace. D atoms with low translational energy release may

also be detected but are spread out in time. The orange trace was simulated using an input translational energy distribution peaking around 3.0 eV (inset of Fig. 7) with an isotropic angular distribution. Even for events with a high translational energy release (>3 eV), the orange trace is restricted by conservation of energy, and the remainder of the fit is captured by noise, which would be expected in the all fragment time-of-flight distribution.

e. Branching ratios

Table 1 presents the experimental branching ratios from the coincidence data for $i\text{-C}_3\text{H}_7\text{O}$ dissociation. Branching ratios are acquired from the raw experimental counts in each channel and corrected using a one-particle detection probability of $p_{\text{one-particle}} = 0.6$.³⁹ By extension, two- and three-body events are corrected using $p_{\text{two-body}} = 0.36$ and $p_{\text{three-body}} = 0.22$. The errors associated with each branching ratio are the standard deviation of the ratios across a collection of data sets meaning that they are random, not systematic errors. The production of channel 5 is about half that of channel 1/3 and thereby contributes to the total photofragment yield in a significantly larger quantity than is predicted by the RRKM results in Table 2.

Table 1: Experimental Branching Ratios for $i\text{-C}_3\text{H}_7\text{O}$		
Channel	Percentage of Coincident Total Events	Percentage of Total Events from Noncoincidence Simulations (from deuterated results)
$i\text{-C}_3\text{H}_7\text{O} \rightarrow \text{CH}_3 + \text{C}_2\text{H}_4\text{O}$ (1 or 3)	$54 \pm 3 \%$	45 %
$i\text{-C}_3\text{H}_7\text{O} \rightarrow \text{OH} + \text{C}_3\text{H}_6$ (5)	$34 \pm 3 \%$	29 %
$i\text{-C}_3\text{H}_7\text{O} \rightarrow \text{H} + \text{C}_3\text{H}_6\text{O}$ (2 or 4)	N/A	16 %
$i\text{-C}_3\text{H}_7\text{O} \rightarrow \text{CH}_3 + \text{CH}_4 + \text{CO}$ (9)	$8.0 \pm 0.7 \%$	7 %
$i\text{-C}_3\text{H}_7\text{O} \rightarrow \text{CH}_3 + \text{CH}_3 + \text{HCO}$ (10)	$4.0 \pm 0.4 \%$	3 %

The three-body branching ratios indicate that channel 9 forms twice as frequently as channel 10. Due to the ambiguity in masses, it is useful to also examine the branching ratio for the dissociation of $i\text{-C}_3\text{D}_7\text{O}$. In doing so, we find that channel 9 still dominates over channel 10 slightly with a ratio of $1.3 \pm 0.3 : 1$.

The right most column presents the branching ratio results from the noncoincidence simulations that include the $\text{D} + \text{C}_3\text{D}_6\text{O}$ channel. The other channel contributions have been adjusted for the ratios observed through coincident detection (i.e. those ratios in the middle column). Perhaps the most important takeaway from these ratios is that the D/H atom loss accounts for less than either

of the other two-body channels but is nevertheless significant.

f. RRKM calculations

Understanding the dynamics of dissociation can be substantially aided through Rice-Ramsperger-Kassel-Marcus calculations⁴⁰ in which the microcanonical rate constant $k(E)$ is given by

$$k(E) = \frac{W^\ddagger(E-E_0)}{h\rho(E)} \quad (14)$$

where h is Planck’s constant, $\rho(E)$ is the density of states of the reactant, and $W^\ddagger(E - E_0)$ is the sum of states of the transition state structure. Geometries and vibrational frequencies of structures in Figure 1 were calculated using the B3LYP/aug cc-pVDZ level of theory⁴¹ and energies of stationary points and transition states were taken from Reference 5. The Beyer-Swinehart algorithm was used to determine the density and sum of states used in the calculations.⁴² Table 2 presents the rate constants for the dissociation of *i*-C₃H₇O into two-body products.

Table 2: RRKM Rate Constants for the Dissociation of <i>i</i> -C ₃ H ₇ O	
Channel	Rate (s ⁻¹)
<i>i</i> -C ₃ H ₇ O → CH ₃ + CH ₃ CHO (acetaldehyde) (1)	3.9×10^{13}
<i>i</i> -C ₃ H ₇ O → CH ₃ + C ₂ H ₃ OH (vinyl alcohol) (3)	2.2×10^{10}
<i>i</i> -C ₃ H ₇ O → H + (CH ₃) ₂ CO (acetone) (2)	6.6×10^{12}
<i>i</i> -C ₃ H ₇ O → H + C ₃ H ₅ OH (2-propenol) (4)	6.3×10^{11}
<i>i</i> -C ₃ H ₇ O → CH ₃ C(OH)CH ₂	1.4×10^{11}
<i>i</i> -C ₃ H ₇ O → OH + C ₃ H ₆ (5)	1.2×10^{11}

For two-body dissociation, channel 1 is predicted to be the fastest, closely followed by H loss. However, the channel 1 rate is on the order of 10^{13} s⁻¹ and thus occurs on a timescale of 25 fs which is much faster than the timescale on which energy randomization occurs.⁴³ H loss is predicted to occur an order of magnitude slower, but still at the edge of what might be expected for a statistical process. These observations suggest that RRKM cannot treat either channel accurately.

RRKM calculations were also performed for the three-body channels. As will be discussed in Section 4.b, the dissociation of acetaldehyde (CH₃CHO) has historically demonstrated interesting dynamics leading to either CH₃ + HCO or CH₄ + CO products.⁴⁴⁻⁵³ For the purposes of this work,

the rate for each pathway was calculated with the respective rates referring to the pathways in Figure 8 below, but given the extensive work in the literature regarding theoretical understanding of CH₃CHO, these results are presented in the supplementary material.

4. Discussion:

This work aims to understand not only the primary products of the dissociation of *i*-C₃H₇O, but also the mechanism through which products form. Therefore, we examine the translational energy distributions more closely. In the most straightforward of instances, ground state mechanisms are typically characterized by translational energy distributions peaking near 0 eV associated with an isotropic angular distribution. In contrast, excited state dynamics typically exhibit translational energy distributions peaking away from 0 eV (close to their $E_{T,MAX}$) with an anisotropic angular distribution.

a. Two-body dissociation

The two-body dissociation of *i*-C₃H₇O leads to CH₃ loss + C₂H₄O (channel 1 and/or 3), channel 5 (OH + C₃H₆), and channel 2 or 4 (H + C₃H₆O). We cannot distinguish between channels 1 (CH₃ + CH₃CHO) and 3 (CH₃ + C₂H₃OH) by mass, but of the two relatively low energy channels, CH₃ + CH₃CHO (channel 1) is ~ 0.4 eV lower in energy. Additionally, channel 3 requires that *i*-C₃H₇O must first isomerize to CH₃CH(OH)CH₂·, in which the lone electron is on a terminal carbon, prior to dissociating. Thus, channel 1 is a more likely candidate. Moreover, the dissociation of acetaldehyde has been thoroughly explored and the observed three-body channels bolster our argument that the C₂H₄O is indeed acetaldehyde. As such, we move forward employing this assumption.

The translational energy distribution of channel 1 in Fig. 4a presents a broad distribution peaking substantially away from 0 (~1-1.5 eV) that is associated with a somewhat anisotropic angular distribution. This suggests that channel 1 does not form through statistical dissociation on the ground electronic state. Although excited state dissociation is possible, the translational energy distribution peaks substantially below $E_{T,MAX}$, in contrast to the photodissociation of CH₃O to CH₃ + O.^{8,37} Additionally, any CH₃CHO formed with < 1.05 eV of translational energy will

have sufficient internal energy to dissociate further, ultimately yielding a three-body event. As much of the intensity in Fig. 4a is above 1.05 eV, it is clear that there is substantial true two-body product yield.

Channel 2 or 4 ($\text{H} + \text{C}_3\text{H}_6\text{O}$) is identified as a product channel through the noncoincidence time-of-flight simulations discussed in Section 3.d. The input translational energy distribution for this channel peaks around 3 eV, substantially away from zero, but still ~ 1 -1.5 eV below $E_{\text{T,MAX}}$ for channel 2. Note that we are blind to the heavy fragment for lower translational energy release events (those with translational energy less than ~ 0.9 eV). As such, the simulations in Section 3.d are mostly useful through their confirmation that $\text{H} + \text{C}_3\text{H}_6\text{O}$ is a valid product channel.

In Fig. 4b, the translational energy distribution for dissociation of *i*- $\text{C}_3\text{H}_7\text{O}$ to channel 5 ($\text{OH} + \text{C}_3\text{H}_6$) is much more characteristic of a statistical ground state dissociation mechanism, in which there is little translational energy imparted to the fragments and the associated angular distribution is fairly isotropic. However, in examining the RRKM calculations in Table 2, we see that channel 5 is predicted to form more slowly than channels 1 and the H loss channels (2 or 4) because of the high barrier to isomerization (TS3 in Fig. 1) that must occur prior to dissociation. Thus, it is not clear that we would even observe channel 5 were it forming on the ground electronic state, but it contributes significantly to the observed photofragment yield and the translational energy and angular distributions are most consistent with ground state dynamics.

These combined observations suggest that statistical dissociation on the ground electronic state is not occurring to yield the two-body product channels, but rather that nonstatistical behavior on the ground electronic state is most consistent with the experimental results. Channels 1 and 2 are not adequately treated by RRKM (they are too fast), but the translational energy distribution for channel 1 peaks far below $E_{\text{T,MAX}}$ and the angular distribution is only slightly anisotropic. As such, internal conversion to the ground electronic state followed by nonstatistical dissociation is likely the best explanation for channels 1 and 2. Channel 5 formation is associated with translational energy and angular distributions that are characteristic of statistical ground state dissociation but its formation is statistically disfavored on the ground electronic state. One possible explanation is that isomerization occurs on an excited electronic state rapidly enough to

compete with internal conversion to the *i*-C₃H₇O structure that dissociates to channels 1 and 2. After this, the CH₃CH(OH)CH₂ can dissociate to channel 5 either on an excited state or subsequent to internal conversion to its ground state; the translational energy and angular distribution for this channel support the latter process.

We can compare our results to the photodissociation of C₂H₅O in a similar energy regime. Experiments performed in this laboratory over a decade ago dissociated C₂H₅O using 5.17 eV.⁸ The translational energy distribution of C₂H₅O → CH₃ + CH₂O was broad, peaking around 1.5 eV and tailing off until ~3.0 eV with an anisotropy parameter $\beta_{lin} = 0.33$. These results are similar to those observed here for channel 1 formation. The authors used RRKM calculations and an anisotropic angular distribution to suggest that dissociation to OH + C₂H₅ also does not occur on the ground electronic state following statistical decomposition. Noncoincidence time-of-flight simulations were used to determine that H + C₂H₄O accounted for 36% of the total photofragment yield, more than is observed in *i*-C₃H₇O. Overall, the conclusion of the C₂H₅O work was unsettled regarding the dissociation mechanisms yielding the products but the authors suggest that at energies 4-5 eV above the respective dissociation barriers, dissociation is just too fast on the ground electronic state to come from full statistical redistribution of the internal energy. This argument is similar to that what is observed in this work, specifically that the RRKM rates are too fast for CH₃ and H loss to come from statistical decay and that OH loss contributes more than RRKM rates suggest it should. Therefore, nonstatistical dissociation on the ground state is most consistent with the observed results.

b. Three-body dissociation

We are also interested in categorizing the formation of channels 9 (CH₃ + CH₄ + CO) and 10 (CH₃ + CH₃ + HCO), which most likely arise from secondary dissociation of acetaldehyde (CH₃CHO) formed in channel 1. These account for about 12% of the coincident dissociation events observed. As discussed in the preceding section, any CH₃CHO formed in a two-body dissociation event with less than 1.05 eV of translation energy can in principle have enough energy to dissociate further to either CH₃ + HCO (channel 10) or CH₄ + CO (channel 9) assuming no internal excitation of the CH₃ co-fragment. The Dalitz plots in Figs. 6a and 6b are indicative of a mechanism in which a CH₃ fragment contains a relatively consistent fraction of

the translational energy release, which would be true if CH₃ leaves first. The remaining three-body products then stem from CH₃CHO secondary dissociation.

The unimolecular decomposition of CH₃CHO has been the subject of numerous experimental⁴⁴⁻⁵³ and theoretical studies⁵⁴⁻⁶³ because it is a small, model system that, in some instances, involves a “roaming” transition state to yield CH₄ + CO products. Figure 8 depicts a basic potential energy surface for decay channels from CH₃CHO with energies referenced to *i*-C₃H₇O. In general, it has been found that CH₄ + CO can form through a tight 3-center transition state⁵⁶ (over a ~ 3.9 eV barrier) or through a roaming mechanism in which ground state CH₃CHO decays to CH₃ + HCO but the CH₃ abstracts H as it departs, ultimately producing CH₄ + CO.^{45,54} In addition to CH₄ + CO products, CH₃CHO can dissociate into CH₃ + HCO via two mechanisms.^{46,50,63} Specifically, C-C bond cleavage in vibrationally-excited ground state (S₀) CH₃CHO can occur through a loose transition state. Alternatively, the electronically-excited triplet state (T₁) of CH₃CHO can decay over a small barrier.

Figure 8: Potential energy surface for relevant decay channels of acetaldehyde. The orange pathways represent those that lead to channel 9 ($\text{CH}_3 + \text{CH}_4 + \text{CO}$), and the blue pathways represent those to channel 10 ($\text{CH}_3 + \text{CH}_3 + \text{HCO}$). The rate constants marked refer to that specific pathway and correspond to the associated value in Table 1. Energies for those pathways were acquired from References 54 and 55.

The dynamics regarding $i\text{-C}_3\text{H}_7\text{O}$ dissociation to channel 9 ($\text{CH}_3 + \text{CH}_4 + \text{CO}$) and channel 10 ($\text{CH}_3 + \text{CH}_3 + \text{HCO}$) are further ambiguous because we are investigating the secondary dissociation of CH_3CHO . As such, we have limited information about the internal energy of CH_3CHO and its effect on competing decay mechanisms. Much of the work examining CH_3CHO photolysis involves excitation to the S_1 state that can undergo intersystem crossing to the T_1 state or internal conversion back to the ground electronic state.^{51,53,65} We assume in this work that we are making channel 1 products in their ground electronic states. It has been shown^{51,53,65} in numerous instances that dissociation of CH_3CHO on its S_0 potential energy surface can yield both $\text{CH}_4 + \text{CO}$ (channel 9) and $\text{CH}_3 + \text{HCO}$ (channel 10). The translational energy distributions for each channel in this work look markedly similar, perhaps in part due to misassignment the

channels. The high energy tail in Figure 5a is the only true indicator of a difference in behavior of the two channels. Additionally, our experimental branching ratios (including those for the dissociation of the deuterated isotopologue) suggest that we do observe both channels. Given that the CH_3CHO produced from channel 1 should have a range of internal energy depending upon the translational energy release of channel 1 *and* the internal energy of the CH_3 co-fragment, it is reasonable to expect that we observe both decay channels from CH_3CHO and that they are produced on the S_0 state of CH_3CHO . As has been shown,^{53,54,65} the observation of roaming to yield $\text{CH}_4 + \text{CO}$ is highly dependent upon the available energy to CH_3CHO as it proceeds through the loose transition state to $\text{CH}_3 + \text{HCO}$. Therefore, as CH_3CHO could have variable internal energy after its initial formation, we cannot be confident as to whether or not a roaming mechanism is observed here.

5. Conclusions:

The photodissociation dynamics of *i*- $\text{C}_3\text{H}_7\text{O}$ have been investigated using photofragment translational spectroscopy at 248 nm. The photofragment yield is dominated by two-body dissociation to $\text{CH}_3 + \text{CH}_3\text{CHO}$ and $\text{OH} + \text{C}_3\text{H}_6$ with some contribution from $\text{H} + \text{C}_3\text{H}_6\text{O}$. The experimental translational energy distributions and RRKM calculations indicate that dissociation occurs primarily on the ground electronic state in a nonstatistical manner. A small amount of three-body dissociation also contributed to the total photofragment yield. Following the production of $\text{CH}_3 + \text{CH}_3\text{CHO}$, any CH_3CHO with sufficient internal energy can dissociate on its ground electronic state to ultimately yield $\text{CH}_3 + \text{CH}_3 + \text{HCO}$ or $\text{CH}_3 + \text{CH}_4 + \text{CO}$. Dalitz plots indicate that this occurs in a sequential manner in which sufficient time passes between the formation of $\text{CH}_3 + \text{CH}_3\text{CHO}$ and the secondary dissociation of CH_3CHO to products.

The similarity of the behavior of *i*- $\text{C}_3\text{H}_7\text{O}$ and $\text{C}_2\text{H}_5\text{O}$ radical photodissociation leave several questions unanswered regarding the exact nature of the dynamics that yield ground state products. Future explorations into these small alkoxy systems should focus on identifying how these mechanisms occur. Nevertheless, it's clear that even the simplest of these radicals exhibit complex behavior that is pertinent to their overarching behavior in more involved chemical reactions in the atmosphere and combustion.

Supplementary Material for Photodissociation of *iso*-Propoxy (*i*-C₃H₇O) Radical at 248 nm
Erin N. Sullivan, Steven Saric and Daniel M. Neumark¹

Department of Chemistry, University of California, Berkeley, California 94720, USA
and Chemical Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, California 94720, USA

Figure S1: Experimental and simulated mass distributions. Panels a and b present the fitted mass distributions in red assuming the presence of channels 1 (CH₃ + CH₃CHO) and 5 (OH + C₃H₆) for the results using $\lambda_{detach} = 532$ nm and 655 nm, respectively. Panels c and d present the fitted distributions assuming that channel 8 (O + C₃H₇) is an additional channel, again at both detachment wavelengths. In the latter distributions, the best fit was found when the contribution of channel 8 was 0%, thereby confirming our analysis that channels 1 and 5 are the predominant two-body dissociation channels.

Figure S2: Comparison of the experimental translational energy distribution for the formation of channel 11 ($\text{CH}_3 + \text{H} + \text{C}_2\text{H}_3\text{O}$) and a simulated distribution in which an additional particle hitting the detector is assigned to a three-body event involving H loss.

Figure S3: Panel a presents a comparison of translational energy distributions for dissociation of $i\text{-C}_3\text{H}_7\text{O}$ to channel 1 ($\text{CH}_3 + \text{CH}_3\text{CHO}$) using different detachment wavelengths to generate the initial $i\text{-C}_3\text{H}_7\text{O}$ radical. 655 nm (1.89 eV) detachment wavelength is shown in orange and is just above the electron affinity of the neutral radical. 532 nm (2.33 eV) detachment wavelength is shown in green. Panel b presents the translational energy distributions for experiments performed using 532 nm as the detachment wavelength and 248 nm as the dissociation wavelength (shown in black) and with only the detachment laser on (shown in red). These experiments demonstrate the dissociation of $i\text{-C}_3\text{H}_7\text{O}$ from just the 532 nm detachment laser.

Figure S4: Channels 1 and 5 experimental translational energy distributions shown in the black with the corresponding prior distribution shown in red. Vibrational frequencies were determined via Ref. 3

RRKM Results for Acetaldehyde Dissociation

The energy and vibrational frequencies of the roaming transition state to $\text{CH}_4 + \text{CO}$ were acquired from Harding et al.,¹ and energies for the other tight transition states were acquired from Reference 2. For the dissociation to $\text{CH}_3 + \text{HCO}$ and $\text{H} + \text{C}_2\text{H}_3\text{O}$ from ground state CH_3CHO , variational transition state theory was used with vibrational frequencies calculated at the B3LYP/aug-cc-pVDZ level of theory.³ For dissociation to $\text{CH}_3 + \text{HCO}$, the C-C bond distance was found to be 4.9 angstroms.

Table S1: RRKM Rate Constants for the Dissociation of CH_3CHO	
Channel	Rate (s^{-1})
$\text{CH}_3\text{CHO} \rightarrow \text{CH}_3 + \text{HCO}$ (10) (k_{triplet})	3.6×10^{12}
$\text{CH}_3\text{CHO} \rightarrow \text{CH}_3 + \text{HCO}$ (10) (k_{loose})	4.7×10^8
$\text{CH}_3\text{CHO} \rightarrow \text{CH}_4 + \text{CO}$ (9) (k_{tight})	4.0×10^8
$\text{CH}_3\text{CHO} \rightarrow \text{CH}_4 + \text{CO}$ (9) (k_{roam})	9.5×10^{10}
