Abstract

Novel MRI-based dynamic cerebral autoregulation (dCA) assessment enables the estimation of both global and spatially-discriminated autoregulation index values. Before exploring this technique for the evaluation of focal dCA in acute ischaemic stroke (AIS) patients, it is necessary to compare global dCA estimates made using both TCD and MRI. Both techniques were used to study 11 AIS patients within 48 hours of symptom onset, and 9 healthy controls. dCA was assessed by the rate of return of CBFV (R_{turn}) following a sudden drop induced by the thigh cuff manoeuvre. No significant between-hemisphere differences were seen in controls using either the TCD or MRI technique. Inter-hemisphere averaged R_{turn} values were not different between TCD (1.89 ± 0.67 %/s) and MRI (2.07 ± 0.60 %/s) either. In patients, there were no differences between the affected and unaffected hemispheres whether assessed by TCD (R_{turn} 0.67 ± 0.72 vs. 0.98 ± 1.09 %/s) or MRI (0.55 ± 1.51 vs. 1.63 ± 0.63 %/s). R_{turn} for both TCD and MRI was impaired in AIS patients compared to controls in both unaffected and affected hemispheres (ANOVA $p=0.00005$). These findings pave the way for wider use of MRI for dCA assessment in health and disease.

acute ischaemic stroke, cerebral autoregulation, magnetic resonance imaging, thigh cuff, transcranial Doppler ultrasound

INTRODUCTION

Cerebral autoregulation (CA) can be estimated from the cerebral blood flow velocity (CBFV) measured with transcranial Doppler (TCD) ultrasound, in both healthy and acute ischaemic stroke (AIS) populations (1-3). TCD is a non-invasive and relatively straightforward technique, able to assess CBFV with good time resolution, making it an attractive method for assessing CA. However, one major limitation of the technique is its poor spatial resolution. Although it is also possible to insonate anterior and posterior cerebral arteries, in most clinical studies, measurements are only made in the middle cerebral arteries (MCAs), thus limiting the detection of CBF abnormalities to differences between the hemispheres in the MCA territories (2, 3). Greater spatial discrimination in CA assessments would be highly desirable. Of the potential imaging techniques, magnetic resonance imaging (MRI) appears suitable because it is available in acute care situations, gives good spatial resolution and has an excellent safety record.

The thigh cuff (THC) manoeuvre is an accepted stimulus for assessing CA, since it induces a rapid drop in blood pressure (BP) due to the reactive hyperaemia in the legs after the temporary ischaemia resulting from the inflated thigh cuffs (1). An earlier study from our group in healthy control subjects has shown the response to a BP fall induced by thigh cuff release is similar when assessed by MRI and TCD; moreover the MRI data may be more reliable (4).

The aim of this study was to compare the ability of the two techniques to discriminate between the healthy and AIS populations.

AIS patients admitted to the University Hospitals of Leicester NHS Trust within 48 hours of symptom onset were studied. Unconscious patients and those with atrial fibrillation were excluded, as were patients with a past medical history or evidence at the time of study of diabetes mellitus, impaired renal function, acute myocardial infarction, and/or unstable angina.

In addition, a control group of 10 healthy subjects of similar age, sex, and BP was recruited from departmental volunteers and advertisement responders. Controls were excluded if they had a history of cardiovascular disease, migraine, epilepsy, or other chronic neurological disorders, or if they had contraindications to MRI scanning.

The study was approved by the Leicestershire, Northamptonshire and Rutland Research Ethics Committee (REC 09/H0403/25), and all subjects gave written informed consent.

Study Protocol

The study protocol consisted of two parts: TCD and MRI measurements, where MRI scans always followed TCD, with a median time interval between them of two hours (range 0.5 to 8 hrs). The two procedures are summarised below.

Initial TCD assessments were performed in a dedicated cardiovascular research laboratory, which was at controlled temperature (20-24°C) and free from distraction. Subjects did not consume caffeine or alcohol for at least 2 hours prior

1
2
3 to study participation. Subjects were asked to lay supine, with arms resting by
4 their sides, and pillows were used for head support. Casual BP was measured at
5 the upper arm using a validated cuff device (Omron Automatic BP 705CP-11,
6 Omron Healthcare, Inc., Lake Forest, IL, USA). Continuous BP was measured
7 non-invasively using a finger arterial volume clamping device (Finapres, Finapres
8 Medical Systems BV, Amsterdam, The Netherlands), with the BP cuff applied to
9 the middle phalanx of the middle finger of the hand opposite to where the arm cuff
10 was applied. A 3-lead surface ECG was recorded continuously. End-tidal CO₂
11 (EtCO₂) was monitored using a capnograph (Capnocheck Plus, Smiths Medical,
12 Ashford, Kent, UK) attached to a nasal cannula.

25
26 TCD ultrasonography (Viasys Companion III, Viasys Healthcare, Surrey, UK) was
27 used to measure CBFV in the left and right middle MCAs simultaneously. Two
28 transducers operating at 2 MHz were positioned on the temporal bone, and the
29 MCAs were identified by adjusting the positions of the transducers to give the
30 maximum reflected signal at a depth of 45-60 mm. The transducers were then
31 secured in position using a head frame.

40 Each subject rested for a stabilisation period of 15 minutes, following which
41 brachial BP was measured using the arm cuff. BP, ECG, EtCO₂ and CBFV
42 recordings were made in each subject before, during and after a step BP drop.
43 The servo-adjust function of the Finapres was turned off at the beginning of each
44 recording and the BP signal was calibrated for each measurement. Digitised
45 signals for all parameters were stored through a physiological data acquisition
46 system for offline analysis.

3
4 The thigh cuff technique was used to induce a step drop in arterial BP. Large thigh
5
6 cuffs (Model C22, DE Hokanson, Inc, Bellevue, WA, USA) were placed one on
7
8 each thigh approximately 10 cm above the knee, and inflated at least 20 mmHg
9
10 above peak systolic BP. An adapted bicycle pump was used for cuff inflation, and
11
12 inflation was maintained for 3 minutes. A transient BP drop was then induced by
13
14 fast simultaneous release of both cuffs using a rapid cuff deflator (Hokanson
15
16 model RD2).
17
18

19
20 Each participant underwent an initial baseline recording of 5 minutes, following
21
22 which 3 repeats of the BP step drop procedure were performed, each one with a
23
24 3-minute period of cuff inflation, and 2 minutes post deflation. The recordings for
25
26 each subject were carried out in a single session, during which the volunteer
27
28 remained supine.
29

30
31 All MRI measurements were performed using a 1.5 Tesla MRI scanner
32
33 (Symphony, Siemens AG, Erlangen, Germany) with a single channel
34
35 transmit/receive quadrature birdcage head coil. After arrival at the MRI suite and
36
37 being seated for a period of 10 minutes, brachial BP was measured as a guide for
38
39 thigh cuff inflation pressure. Subjects then lay supine on the scanner couch and
40
41 the thigh cuffs were applied. A lightweight foam collar was used to support the
42
43 head and neck, and a custom-made foot rest was clamped to the couch to provide
44
45 additional support during the cuff deflation manoeuvre in order to minimise
46
47 movement. The foot rest was a wooden plate that projected upwards from the
48
49 couch and which was adjustable to provide a firm base against which the subjects
50
51 could brace their feet at a comfortable ankle flexion angle.

1
2
3
4 After a localizer scan, standard proton-density / T₂-weighted dual-echo fast spin-
5
6 echo and spin-echo echo-planar imaging (EPI) diffusion-weighted (DW)
7
8 sequences were performed so that any ~~existing~~ acute stroke pathology could be
9
10 identified by an independent stroke consultant who was blind to all other details of
11
12 the study. The sequence parameters for the dual-echo scan were: TR=2930 ms;
13
14 TE=15,86 ms; echo train length=5; matrix=256×256; in-plane
15
16 resolution=0.9×0.9 mm. For the DW sequence, the parameters were:
17
18 TR=4100ms; TE=112ms; matrix=128×128; in-plane resolution=1.8×1.8 mm
19
20 interpolated to 0.9×0.9 mm. Diffusion weighting was applied in three orthogonal
21
22 directions, with a b-factor of 1000 s mm⁻²; an image with b=0 was also collected.
23
24 For both sequences, 21 axial slices were acquired, with a slice thickness of 5 mm
25
26 and a 2 mm gap between slices, covering the whole of the cerebrum. Slices were
27
28 positioned parallel to a line that joined the most antero-inferior and postero-
29
30 inferior margins of the corpus callosum as viewed on a sagittal localizer,
31
32 correcting for any head tilt by also viewing in the coronal plane.
33
34
35
36

37
38 The thigh cuffs were then inflated to at least 20 mmHg above peak systolic BP
39
40 and the main image series was commenced as soon as the cuffs were up to
41
42 pressure. This consisted of rapid serial acquisition using a gradient-echo EPI
43
44 sequence (TR=1000 ms; TE=40 ms; flip angle=40°; matrix=64×64; in-plane
45
46 resolution=3.45×3.45 mm; slice thickness=5 mm; gap between slices=4 mm).
47
48 Twelve slices were positioned as for the dual-echo and DW scans, but there was
49
50 less coverage of the cerebrum due to the smaller number of slices acquired. Two
51
52 hundred and forty multi-slice image sets were acquired over four minutes,
53
54 equivalent to a sampling frequency of 1 Hz, which was the fastest rate possible
55
56 while still maintaining coverage of the head. The relatively low resolution of the
57
58
59
60

1
2
3 image matrix (4096 voxels per slice) was also because of the need for high
4
5 sampling frequency. Three minutes into the series, the cuffs were rapidly deflated.
6
7
8 It has previously been found to be necessary to inflate the thigh cuffs for three
9
10 minutes prior to deflation, in order to obtain a reliable BP drop (5). Although we
11
12 ultimately only characterize the MRI signal change after deflation in order to
13
14 assess autoregulation, it is advantageous to scan for the full four minutes to
15
16 minimize any change in stress to the subject (due to the acoustic noise during
17
18 MRI scanning) around the time of the thigh cuff release. This also allowed us to
19
20 assess and correct any signal changes due to physiological 'noise', as done for
21
22 similar scanning protocols such as functional MRI (fMRI) analysis (6). After the
23
24 scan was completed, the cuffs were re-inflated and the procedure was repeated
25
26
27
28 twice more. The scanning for each subject was carried out in a single session,
29
30 during which the volunteer remained supine without being removed from the
31
32 scanner.
33

34 35 **Data Analysis**

36 37 *TCD*

38
39 Data acquired were edited using application-specific software designed in house,
40
41 prior to calculation of dCA values. CBFV traces were visually inspected and
42
43 passed through a median filter. The right and left CBFV, BP, ECG, and EtCO₂
44
45 were then low-pass filtered (Butterworth, 20Hz cut-off). Recordings were rejected
46
47 if there was a drift in BP signal, absent or poor quality CBFV signal over several
48
49 beats, or a large number of narrow spikes (7). The ECG was marked to determine
50
51 the R-R interval, and estimates of mean CBFV and BP were calculated for each
52
53 cardiac cycle. The end tidal value of the capnographic signal was detected for
54
55
56
57
58
59
60

1
2
3 each breath and resampled for each cardiac cycle. Using spline interpolation and
4
5
6 resampling the data at 5 Hz, a uniform time base for all the data was achieved.
7

8 *MRI*

9
10 MR image pre-processing was performed using the FMRIB Software Library (FSL)
11
12 Version 4.1.7 (www.fmrib.ox.ac.uk/fsl). This consisted of: noise reduction using
13
14 an anisotropic spatial filter, correction for subject motion during the acquisition,
15
16 and registration to a standard anatomical space in order to allow data averaging
17
18 across subjects. The time-series of images for each subject was spline
19
20 interpolated and resampled at 5Hz similarly to the TCD data.
21
22
23

24
25 Due to the occurrence of artefacts in the MRI signals and, to a lesser extent, in the
26
27 TCD CBFV signals, acceptance of data was based on a blind procedure to avoid
28
29 any potential biases. Both TCD and MRI signals were low-pass filtered at 0.35 Hz
30
31 and their amplitude was normalised by fitting the signals' minimum and maximum
32
33 values within the range [0,1]. This procedure which made signals indistinguishable
34
35 between modalities (Fig. 1). TCD and MRI signals were then mixed randomly and
36
37 presented on a computer screen to a panel of four of the authors (RBP, NPS,
38
39 MAH, TGR) to decide on acceptance/rejection based on the expected temporal
40
41 pattern after cuff release and the absence/presence of large artefacts that could
42
43 distort estimates of the rate of return. Unanimity was required for acceptance.
44
45
46

47 *Dynamic CA*

48
49 With TCD, the efficiency of dCA using the THC approach has been quantified with
50
51 the ARI index (5, 8). For the MRI signal response to the THC manoeuvre, an
52
53 equivalent index has been proposed (9), but in the current study an alternative
54
55 approach was adopted to obtain an homogenous index for both signals, taking
56
57
58
59
60

1
2
3 into account the absence of BP recording concurrent with the MRI signal.
4
5 Following the THC release, both the TCD CBFV and the MRI signal drop sharply
6
7 and then recover to their original level with a speed of recovery that is assumed to
8
9 reflect the efficiency of dCA (1). The rate of return index (R_{turn}) is the slope of the
10
11 return phase in units of %/s (Fig. 1), calculated from the linear regression of 30
12
13 data samples (6 s) following the minimum signal value after cuff release (< 5 s),
14
15 normalised by the signal standard deviation for the data window ranging from 15 s
16
17 before to 15 s after cuff release.
18
19

20 21 22 *Statistical Analysis*

23
24 R_{turn} values for the left and right hemispheres of control subjects, for each
25
26 technique (TCD and MRI), were tested for differences with a paired Student's t-
27
28 test and averaged if non-significant. A two-way ANOVA was performed to assess
29
30 the differences between control subjects and the affected and unaffected
31
32 hemispheres (*condition*) and differences between TCD and MRI (*technique*). ROC
33
34 curves were constructed and the ability of both TCD and MRI to detect stroke in
35
36 the ipsi- and contra-lateral hemispheres was assessed using the area-under-the
37
38 curve (AUC). Confidence limits for differences between two AUCs were obtained
39
40 by Monte-Carlo simulations, using 10^5 realizations with random gaussian
41
42 distributed data fitting the exact number of subjects and statistical distributions of
43
44 corresponding R_{turn} values. The level of statistical significance was set at $p < 0.05$
45
46
47 for all tests.

Results

Most patients were studied within a 48 hour window after stroke onset, but for logistic reasons involving the MRI test, three patients were studied at 54, 55 and 73 hours after onset, respectively. The overall distribution (median [lower,upper quartiles]) of measurement times after onset was 44.7 [30.6,54.5] hours. With the exception of one control subject, all participants tolerated the measurement protocol for both TCD and MRI well, with nine control subjects and 11 stroke patients completing three THC manoeuvres in each modality. After careful signal inspection, including the blind presentation and rejection of signals with artefacts coinciding with THC release, the resulting number of recordings (separate hemispheres) for analysis was 37 and 26 for TCD controls and patients, respectively, and 44 and 24 for MRI.

Baseline subject characteristics are presented in Table 1. There were no significant differences in age or BP between the stroke patients and control subjects, but heart rate was higher and EtCO₂ lower in patients compared to controls.

Fig. 1 contains representative TCD and MRI waveforms for a control subject and a stroke patient, showing the temporal pattern similarity between the two modalities and also between hemispheres. No significant differences were found between the right and left hemispheres in control subjects for either the TCD or MRI. Inter-hemisphere averaged linear regression slopes were not significantly different between TCD and MRI (Table 2). On the other hand, the two-way ANOVA indicated a highly significant difference between stroke and controls ($p=0.00005$),

1
2
3
4 without a difference between modalities ($p=0.23$). *Post hoc* analysis also indicated
5
6 differences amongst the three groups (controls vs. ipsilateral, $p=0.0014$; controls
7
8 vs. contralateral, $p=0.024$; ipsi- vs. contra-lateral, $p=0.0433$). These differences in
9
10 the rate of return following thigh cuff release are confirmed by the coherent
11
12 averages represented in Fig. 2. This figure also depicts the coherent averages of
13
14 BP recorded during the TCD protocol, showing the significant pressure drops
15
16 obtained in both controls and patients.
17

18
19
20 ROC curves are shown in Fig. 3. For both TCD and MRI, detection of ipsilateral
21
22 strokes was significantly better than the classification of contralateral strokes
23
24 (TCD $AUC_{\text{ipsi}}=0.900$, $AUC_{\text{contra}}=0.765$, $p=0.0477$; MRI $AUC_{\text{ipsi}}=0.9775$,
25
26 $AUC_{\text{contra}}=0.708$, $p=0.0283$). No significant differences were observed for AUC
27
28 comparisons between TCD and MRI, neither for the ipsilateral nor the
29
30 contralateral sides.
31
32
33
34
35

36 DISCUSSION

37
38 The aim of this experimental study was to assess the potential of MRI to detect
39
40 impairment of CBF pressure-autoregulation in comparison with the previously
41
42 reported changes observed with TCD in patients with acute ischaemic stroke
43
44 (AIS). The motivation for developing an imaging-based alternative to TCD for
45
46 assessing dynamic CA is that TCD can only measure flow velocity in the major
47
48 cranial arteries that are accessible through the temporal bone window, most
49
50 commonly the MCAs. Thus, impairment to autoregulation can only be assessed
51
52 as an average over large brain areas and is usually taken to be indicative of
53
54 changes at the level of an arterial territory or a brain hemisphere. With the ability
55
56
57
58
59
60

1
2
3 of MRI to capture images of the whole brain, this introduces the possibility to
4 evaluate focal changes.
5
6

7
8 We compared responses to the sudden release in thigh cuffs (1) using flow
9 velocity values in the left and right MCAs for TCD, and MRI signal intensity
10 responses measured in the left and right hemispheres in image slices
11 corresponding approximately to the MCA territories (Figs 1 & 2). Hence, although
12 we did not fully exploit the imaging capabilities of MRI, the aim was to compare as
13 closely as possible results from the two techniques in an AIS population.
14
15
16
17
18
19
20
21

22 Despite the small number of subjects successfully scanned, AIS patients had
23 evidence of impaired dynamic CA from the MRI responses, similar to TCD,
24 although no differences between the affected and unaffected hemispheres were
25 identified. However, there is conflicting evidence for differences between the
26 affected and unaffected hemispheres of stroke patients, with some researchers
27 reporting a significant difference between hemispheres (10-13), and others
28 reporting no difference (14-17). It was not possible to explore potential differences
29 in the rate-of-return index (R_{turn}) related to stroke subtype, since only 11 of 37
30 recruited AIS patients had good quality data with both TCD and MRI techniques.
31 Furthermore, patients were categorised according to the clinical Oxfordshire
32 Community Stroke Project classification, though the investigation of differences
33 between large vessel and other stroke subtypes (particularly small vessel) using
34 the TOAST classification may have been more informative.

55 *Limitations of the study*
56
57
58
59
60

1
2
3
4 Undoubtedly, the main limitation of our study is the lack of simultaneous
5
6 continuous BP measurement during MRI recordings. We are not aware of any
7
8 noninvasive devices that can provide information similar to the Finapres within the
9
10 environment of the MRI scanner. Despite this limitation, there is no reason to
11
12 believe that the BP drops obtained during MRI recordings were significantly
13
14 different from those achieved during the TCD test, when all participants showed
15
16 significant pressure drops (Fig. 2). Moreover, the sudden MRI signal drop
17
18 following thigh cuff release, and the characteristic pattern of the response, in both
19
20 controls and AIS patients (Figs 1 & 2), also suggest that the BP signal pattern was
21
22 similar for the TCD and MRI recordings.
23
24

25
26 With MRI we also found a worse signal-to-noise ratio compared to the TCD,
27
28 largely due to the presence of motion artefacts. When artefacts occurred before or
29
30 after the 30 s period of thigh cuff release and signal recovery, narrow spikes (<3
31
32 s) could be removed by linear interpolation, but this was not acceptable during the
33
34 30 s window, and in these cases it led to the recording being rejected. Although
35
36 we applied a motion correction scheme to co-register the individual images,
37
38 motion artefacts is one area that needs addressing in future studies. In addition to
39
40 motion artefacts, the need to ascertain that CBF dropped significantly and rapidly
41
42 after cuff release also led to a significant number of recordings being rejected. For
43
44 this reason, having more than one recording in each measurement session is
45
46 paramount to increase the yield of acceptable data in future similar studies.
47
48 The signal-to-noise ratio limitations mentioned above did not allow a more detailed
49
50 examination of regional differences in R_{turm} which is the ultimate objective of this
51
52 line of work. We are still pursuing this objective with more sophisticated image
53

improve prospects in this area. Nevertheless, the demonstration that pathophysiological differences in dynamic CA can be detected with MRI, similarly to that described for TCD, is an important stepping stone for progressing towards testing the hypothesis that acute ischemic events can lead to regional differences in dynamic CA.

As in most studies involving the use of TCD, it is not possible to guarantee that MCA cross-sectional area remained constant during examinations to assume that CBF velocity temporal patterns perfectly matched corresponding changes in absolute CBF. Nonetheless, Newell *et al* (18), using electromagnetic flow meters in the carotid artery, have demonstrated that changes in MCA diameter are unlikely to take place during the thigh cuff manoeuvre. Although small changes in EtCO₂ have been reported following the sudden release of thigh cuffs (19), their amplitude were not sufficient to induce significant changes in MCA diameter (20, 21).

The higher heart rate and lower EtCO₂ in patients, compared to controls, suggests that patients might have demonstrated greater anxiety during recordings than control subjects. We are not aware of any reports in the literature suggesting that relatively small differences in heart rate (~ 10 bpm) could influence dynamic CA.

On the other hand though, it is well known that hypocapnia tends to improve dynamic CA (1) with the implication that if patients had PaCO₂ values closer to those of controls, their values of R_{turn} would be expected to be even lower.

Relative hypocapnia in patients with AIS was also observed in a separate recent study in our lab, involving a completely different group of stroke patients (22).

Finally, due to the lack of BP measurement during the MRI test, we adopted an alternative index of dynamic CA, based on the rate of return of the CBF signal to baseline, following the sudden drop induced by cuff release (Figs. 1 & 2). This index has a similar logic to the rate of regulation (RoR) adopted by Aaslid *et al* (1) in their seminal study and it also has similarities to a recently proposed model-free index of dynamic CA (23). The R_{turn} index represents a relatively simple common metric to assess both types of response (TCD and MRI), following the temporal patterns observed for controls and patients (Figs. 1 & 2). However, it must be made clear that this does not represent a broader proposal to replace indices that have been previously validated, such as the ARI or phase values from transfer function analysis of the BP-CBFV relationship (24).

CONCLUSIONS

Because of its greater spatial discrimination, MRI-based assessment of cerebral autoregulation is an appealing alternative to the current TCD-based methods for exploring regional CA changes as a consequence of AIS and other acquired brain pathologies. We have previously demonstrated that the signal change seen in a gradient-echo MRI sequence is similar to the blood flow velocity change seen using TCD in response to a THC manoeuvre. In the current study, we have been able to show that the MRI method is able to discriminate between healthy controls and stroke patients. The low signal-to-noise ratio in the data we acquired precluded more detailed investigation of any regional variations at this time. The improved signal-to-noise ratio and BOLD contrast when using MRI scanners of higher field strength (25) should lead to a significant improvement in the quality of

measurements, and requires further investigation. Studies with greater statistical power are also needed to shed light into potential inter-hemisphere differences in AIS patients.

ACKNOWLEDGEMENTS

This study was supported by The Stroke Association of the United Kingdom. NPS also received funding from the NIHR BRU for Cardiovascular Sciences. JLJ was partially funded by the University of Santiago de Chile and Becas Chile.

AUTHOR CONTRIBUTION STATEMENT

RBP, MAH & TGR conceptualise and planned study; NJS & MAH performed data collection; NJS, JLJ, MAH & RBP performed data editing and analysis; MAH & RBP wrote manuscript, RBP, JLJ, NPS, MAH & TGR checked manuscript and approved final version.

DISCLOSURE/CONFLICT OF INTEREST

The authors declare no conflicts of interest.

LEGENDS

Figure 1 – Representative MCA velocity (A,C) and MRI intensity signal (B,D) for a control subject (A,B) and a stroke patient (C,D) following thigh cuff release with $t=0$ indicating the minimum negative signal derivative as point of synchronism. Right or ipsilateral hemisphere (continuous line), left or contralateral hemisphere (dashed line). The straight interrupted line represents the regression best fit from the first minima (<5 s) after cuff release for a 6 s interval.

Figure 2 – Coherent population averages of MCA velocity (A,C,E) and MRI intensity signal (B,D,F) for healthy controls (A,B) and contralateral (C,D) and ipsilateral (E,F) hemispheres of stroke patients. For TCD recordings, mean arterial pressure (MAP) is also included (dashed line). Error bars represent the largests ± 1 SE at the point of occurrence.

Figure 3 – Receiver operating characteristic curves for TCD (A) and MRI (B). Ipsilateral hemisphere (continuous line), contralateral hemisphere (dashed line).

TABLES

Table 1. Subject characteristics.

	Controls (n=9)	Stroke Patients (n=11)
Age (years)	62 [46-77]	62 [39-87]
Male / female	7 / 2	8 / 3
Heart Rate (beats/min)	57.2 ± 6.1	67.5 ± 10.2 [#]
Systolic BP (mmHg)	133.6 ± 31.2	135.5 ± 31.4
Diastolic BP (mmHg)	65.6 ± 14.1	62.2 ± 16.0
EtCO ₂ (mmHg)	39.6 ± 2.6	35.5 ± 3.1 [#]
Mean MCA CBFV (cm/s)	(L) 50.9 ± 8.7	(UH) 42.3 ± 9.8
Mean MCA CBFV (cm/s)	(R) 49.5 ± 5.2	(AH) 45.2 ± 8.9

BP: blood pressure; EtCO₂: end-tidal CO₂; CBFV: cerebral blood flow velocity; MCA: middle cerebral artery; L: left hemisphere; R: right hemisphere; AH: affected hemisphere; UH: unaffected hemisphere. Values presented as mean ± standard deviation or median [range]. [#] p<0.05 compared to controls.

Table 2. Linear regression slopes and correlation (r) coefficients for control subjects and acute stroke patients.

<i>Technique</i>		<i>Condition</i>		
		Controls	Ipsilateral stroke side	Contralateral stroke side
TCD	slope (%/s)	1.41 ± 0.42 (n=9)	0.42 ± 0.94 (n=10)	0.61 ± 0.82 (n=9)
	r	0.84 ± 0.11	0.62 ± 0.28	0.60 ± 0.21
MRI	slope (%/s)	1.25 ± 0.73 (n=9)	0.80 ± 0.24 (n=5)	0.96 ± 0.36 (n=8)
	r	0.73 ± 0.29	0.68 ± 0.05	0.68 ± 0.12

Values are mean ± SD.
